HIV incidence

Brazilian Amazon

ABSTRACT

Background: The Amazonas state/AM and Manaus rank among the highest AIDS detection rates in Brazil. High proportion of HIV infected blood donors and transmission clusters of multidrug antiretroviral/ARV resistant viruses were described in HEMOAM blood donors, a main Amazonas public blood bank. Recent and long-term infections among previously genotyped donors are reported.

Methods/materials: The recency immunoassay Lag Avidity EIA (Maxim, USA) was employed. Clinical/CD4/viral load medical file data of the main local HIV management center (FMT-HVD) and ARV treatment/ART data were reviewed.

Results: Among 142 HIV-blood donors, chronic infection predominated ($n = 87$; 61.3%), 79 based on LAg EIA and 8 undisclosed HIV identified in FMT-HVD records, mostly young adult, single males, 4 repeat donors, all ART-naive. Recent infections represented 30.3% ($n = 43$), 39 identified by LAg EIA and 4 immunologic windows (antibody negative/NAT/RNA positive). The overall profile of recent and long-term infections was similar, including moderate rate of transmitted drug resistance/TDR, however with multiple resistance mutations to more than one ARV-class, suggesting ART/failure.

Discussion: Recent/acute and undisclosed/long-term HIV infections represent blood safety alerts suggesting test-seeking behavior of at-risk populations. Early ART use in Brazil, can turn HIV diagnosis more challenging representing a blood transfusion risk in the highly endemic Brazilian Amazon.

In the last decade, the Brazilian AIDS epidemic has declined especially in the Southeast and South regions, contrasting with the consistent increase observed in the North region.

4 In 2021–2022 the Amazonas state/AM, located in the North
5 region, ranked the first and the second highest national AIDS
6 detection rate, and Manaus, its capital, has reported detection
7 rates much higher than the national rate.^{1,2} During the last
8 decade, the Amazonas state reported the highest AIDS inci-
9 dence rate (52.2/100,000 inhabitants) compared to the rate
10 reported in Brazil (21.3/100,000).² These recent epidemiologic
11 data highlight the importance of surveillance and prevention
12 measures for HIV/AIDS in Amazonas and Manaus, located in
13 the Brazilian Amazon.

14 The importance of apparently healthy blood donors as a key
15 sentinel population to monitor infectious diseases, including
16 HIV is well known. Studies from our group have shown high
17 rates of HIV-1 infection among HEMOAM blood donors, a refer-
18 ence public blood bank located in Manaus/AM.^{3,4} More recently,
19 we have described HIV-1 molecular features including genetic
20 subtypes and antiretroviral Transmitted Drug Resistance muta-
21 tions (TDR) among 227 HIV infected blood donors from three refer-
22 ence public blood centers in North Brazil, the great majority
23 ($n = 198$) was from HEMOAM.^{5–8} Molecular epidemiology results
24 of the HIV POL gene of blood donors from HEMOAM showed a
25 strong predominance of subtype B (90 %) with minor circulation
26 of subtypes C, F1 and BF1 recombinants.⁵ Additionally, moder-
27 ate TDR rate (12.6 %) including diverse profiles of multiple drug
28 resistance mutations and the identification of transmission
29 clusters of multidrug-resistant viruses were identified.⁶ These
30 findings emphasize the relevance of special surveillance efforts
31 of the HIV/AIDS epidemic in Amazonas state, including inci-
32 dence studies in specific populations, such as blood donors and
33 the monitoring of TDR rates, which are crucial to orient treat-
34 ment options and to assess proper interventions to control the
35 epidemic.

36 HIV incidence assays, also known as recency assays, can
37 provide incidence estimates by determining recent versus
38 non-recent infections, however, their use is restricted to
39 research and surveillance purposes. These assays are based
40 on biomarkers such as antibody avidity, which is a function
41 of the maturation of the immune response overtime. The lim-
42 iting antigen Avidity Enzyme Immunoassay/EIA LAG was
43 endorsed following the evaluation of seven HIV recency
44 assays using a well-characterized panel of samples from the
45 Consortium for the Evaluation and Performance of HIV Inci-
46 dence.⁹ Thus the Centers for Disease Control and Prevention
47 (USA) developed a LAG assay and transferred the technology
48 to two biotech companies (Sedia and Maxim).¹⁰ A recent sys-
49 tematic review of limiting antigen avidity enzyme immuno-
50 assays for the detection of recent HIV infections reported that
51 these tests can be considered valuable to incidence estima-
52 tion, although different test features can influence results,
53 such as HIV-1 subtypes, population characteristics, assay
54 algorithms and thresholds.¹¹

55 The goal of this study was to describe recent and long-
56 term infections among previously genotyped HIV-1 infected
57 blood donors from HEMOAM/AM based on Lag assay and
58 review of medical file data.^{5,6}

59 Our study population was based on the original 198 HIV-
60 HEMOAM blood donors described^{5,6} from which 142 stored
61 plasma samples were available for testing. The recency LAG
62 Avidity EIA test (Maxim Biomedical Inc., Rockville, MD, USA)
63 was employed for incidence estimation according to

manufacturer's instruction.¹² Briefly, serum dilutions were 64
incubated in 96-well micro titer plates coated with limiting 65
concentration of gp41 (rIDR-M), a multi-subtype recombinant 66
HIV-1 antigen. Low PH dissociation buffer was added, fol- 67
lowed by a goat anti-human IgG conjugated to Horseradish 68
Peroxidase (HRP). Finally, tetra methyl benzidine substrate 69
was added and color generated. The optical density 70
(OD = 450 nm) measured for each sample was normalized 71
using a calibrator tested in triplicate in each plate, and the 72
median of the three ODs was used to normalize specimen 73
readings, producing normalized Optical Density (ODn) meas- 74
urements. Specimens with ODn > 2.0 were considered long- 75
term infections. Specimens producing an initial "screening" 76
ODn ≤ 2.0 were subjected to triplicate "confirmatory" testing 77
and the median ODn of the triplicate results was the final 78
result. Recent infections were defined by ODn values ≤ 1.5 . 79
Additionally, clinical information, CD4 counts and viral load 80
data were retrieved from medical files at Fundação de Medic- 81
ina Tropical, Heitor Vieira Dourado (FMT-HVD), the main pub- 82
lic reference center for HIV management located in Manaus/ 83
AM. ARV treatment/ART data registered at the national online 84
HIV treatment platform of the Ministry of Health (SICLOM) 85
was also revised. 86

87 In this study, acute infections were defined by the blood
88 bank results of serologic immunologic window as HIV sero-
89 negativity and HIV Nucleic Acid Test (NAT) positivity, indicat-
90 ing early infection before seroconversion. HEMOAM
91 implemented NAT – screened donations to decrease the
92 residual risk of immunologic window period transmission in
93 2012.⁴ Recent HIV infection was defined by the use Maxim
94 LAG-Avidity EIA, that applies only to seropositive individuals
95 and is based on the avidity of HIV antibodies, which correlates
96 with infection duration. We have adopted the timing of recent
97 infection indicated by the manufacturing company: 161 days
98 (95 % CI 148–174) at the cutoff ODn ≤ 1.5 . Long-term infection
99 (>161 days) was defined by Lag Avidity assay results and by
100 data retrieved from medical files at FMT-HVD.

101 Statistical analysis was performed with absolute param-
102 eter values. Fisher's exact test was applied for comparisons of
103 sociodemographic parameters among recent and long-term
104 infections, $p < 0.05$ was considered significant. Medians and
105 Interquartile Range (IQR) were applied to CD4 counts and viral
106 load measurements. The Institutional Review Board approved
107 this study (CAEE # 26,904,819.0000.0009).

108 Out of 142 blood-donor samples available, 12 were excluded
109 from LAG testing due to previous knowledge of the timing of
110 infection: four acute cases diagnosed as serologic immunologic
111 window at HEMOAM⁶ and 8 long-term undisclosed cases of HIV
112 infection previously diagnosed at FMT-HVD.

113 LAG avidity EIA results from 130 HIV donors (142–12
114 exclusions) showed that 79 were considered long-term and
115 39 were classified as recent infections; 12 specimens (8.4 %)
116 had indeterminate results. Considering also data retrieved
117 from medical files, long-term infections prevailed in
118 HEMOAM HIV-1 infected blood donors (61.3 %, $n = 87$):
119 based on LAG EIA and 8 based on data from FMT-HVD medi-
120 cal files. Recent HIV-1 infections represented 30.3 % ($n = 43$),
121 39 identified by LAG EIA and 4 acute serologic immunologic
122 window cases (Antibody negative/NAT positive)⁶ identified
123 by the HEMOAM screening.

124 Similar sociodemographic and molecular profiles were
125 observed in recent × long-term HIV infected HEMOAM blood
126 donors: the majority was young (18–30 years), males, singles,
127 with high school degree (Table 1). Repeat donors were 51% in
128 recent infections and 38% in long-term infections. Recent
129 and long-term infections had high proportions of subtype B,
130 BF1 recombinants and subtype F, while subtype C was only
131 detected in long-term infections. According to previous geno-
132 typing data,⁶ the rates of transmitted drug resistance muta-
133 tions in recent and long-term cases were comparable (13.9%
134 and 13.8% respectively).

135 The four acute HIV infections detected in blood donors
136 were young males, and one had a POL sequence (Gen-
137 Bank#MH6731121) that belonged to a transmission cluster of
138 multidrug resistance virus (Table 2). The review of medical
139 files one year after genotyping studies were published^{5,6}
140 showed that 61.9% (88 out of 142) of infected donors were
141 enrolled at the FMT-HVD, the majority (n = 80) was registered
142 after the genotyping study. This review revealed that 5.6% (8
143 out of 142) of donors investigated had a previous diagnosis of
144 HIV infection and were therefore considered as long-term
145 infections (Table 2). Among the 8 HIV undisclosed long-term
146 infected donors, six were males, four were repeat donors, that
147 had made from 1 to 11 blood donations at HEMOAM, all of
148 them before the genotyping study (data not shown). These
149 individuals were mostly young adults (22–40 years), one had a
150 POL sequence with multiple nucleoside and non-nucleoside

reverse transcriptase inhibitor mutations (NRTI/NNRTI) (Gen-
Bank #MH673188.1) (Table 2). According to the review of the
national online HIV treatment platform SICLOM, none of
them was under ART at the time of the blood donation and
the genotyping study.

According to medical files review at FMT-HVD, the median
of the first reported CD4 cell counts in the recent infected
group (n = 24) was 488 cells/ μ L (IQR 346–655 cells/ μ L) and the
median in the long-term infected group (n = 51) was 349 cells/
 μ L (IQR 176–535 cells/ μ L). The median of the first reported
Viral Load (VL) in the recent infected group (n = 22) was
16,066 copies/mL (IQR 2848–71,526 copies/mL) and the median
in the long-term infected group (n = 45) was 45,784 copies/mL
(IQR 8871–169,792 copies/mL). However, it's important to point
out that the first measurements of these parameters were
obtained at different time points post diagnosis, depending
on how long each patient took to search for specialized assis-
tance, thus limiting the value of the association of these
parameters to the time since infection.

In the current study from the Brazilian Amazon, recent
infections including serologic immunologic window cases
and undisclosed long-term HIV infections were identified
among apparently healthy HEMOAM blood donors, reflecting
the highly endemic situation in Amazonas, one of the hottest
spots for HIV-1 transmission in Brazil.^{1,2} Studies in different
HIV infected Brazilian populations have applied diverse
methodologies to distinguish recent from long-term

Table 1 – Main sociodemographic and molecular features of recent and long-term HIV-1 infected HEMOAM blood donors.

178 infections. Two multicenter studies based on Lag avidity
179 assay among blood donors reported HIV incidence among
180 seropositive donors from different geographical Brazilian
181 regions. A study among 246 HIV – seropositive donors from 4
182 different blood centers identified 17.5 % as recent infection, a
183 much lower estimate than the 30.3 % described in the current
184 study.¹³ Another study analyzed 10 year period (2007–2016)
185 incidence in first time and repeat donors from blood centers
186 located in distinct Brazilian regions: Recife, São Paulo and
187 Belo Horizonte and during a shorter period in Rio de Janeiro.
188 Although no blood center from north Brazil was included, this
189 study showed that Recife in the northeast region reported the
190 highest incidence estimates both in first time and repeat
191 donors.¹⁴

192 In our study, undisclosed HIV represented almost 10 % of
193 the long term-infections. Self-report is often used to identify
194 HIV-infected individuals who are not aware of their HIV status,
195 however, the accuracy of this information is limited, as
196 infected individuals may deny their HIV status,¹⁵ similarly to
197 what occurred during the blood bank interview. Undisclosed
198 HIV status may be associated with concern about the confidentiality
199 of the information, or with fear of stigma, discrimination,
200 exclusion from study benefits or interventions, or of
201 other social harms.¹⁶ Although the current study was not
202 designed to identify blood donation motivation, we can speculate
203 test-seeking behavior especially in undisclosed HIV cases,
204 as the blood bank screening was probably used to ratify
205 the HIV diagnosis. Additionally, the finding of one third of
206 HIV infected blood donors with recent infection, including
207 serologic immunologic window cases, which can be considered
208 early cases before seroconversion, corroborates the test-seeking
209 hypothesis of at risk donors, who take advantage of
210 the blood bank screening to monitor their HIV-1 status. This
211 finding raises important blood safety concerns, as it's known
212 that high viral loads during the early HIV infection increase
213 the risk of transmission by blood transfusion. In this context,
214 our results reassure the effective role of the HIV-NAT as an

important additional safety layer to avoid the residual risk of
215 transmission by blood transfusion, especially among serologic
216 immunologic window cases.
217

218 Studies have used retrospective ARV testing in samples as
219 an objective measure to evaluate the accuracy of self-reported
220 HIV status.^{17,18} A study in South African blood donors to enroll
221 HIV elite controllers/EC (Antibody+/RNA-), found upon ARV
222 drugs testing, that almost 70 % of presumed EC were in fact
223 previously diagnosed HIV under ART.¹⁸ In our study, the resistance
224 profiles of HEMOAM blood donors, characterized by the
225 simultaneous detection of multiple ARV resistance mutations,
226 associated to NRTI/NNRTI⁶ suggest ART and failure, however
227 medical files and SICLOM platform revisions could not confirm
228 ART and ARV drugs testing was not available.

229 Studies have shown that early ARV use may reduce both
230 HIV-RNA and antibody levels^{19,20} increasing the difficulties to
231 identify cases of HIV infection among blood donors with
232 undisclosed HIV and under ART. Also, it's possible that effective
233 ART and undetectable viral loads may be misinterpreted
234 by patients as “cure” motivating blood donation to check
235 results by a most reliable serologic and molecular blood bank
236 criterion. Although we cannot estimate the extent of undisclosed
237 HIV and ART among HEMOAM blood donors, HIV positivity
238 and concomitant early ARV use (HIV+/ARV+) may represent
239 a new challenge for the local blood supply safety as recent
240 epidemiologic data showed that the Amazonas has one of the
241 highest AIDS incidence rates in Brazil.^{1,2}

242 In summary our findings of both undisclosed long-term
243 and of recent HIV infections including serologic immunologic
244 window cases among apparently healthy blood donors, some
245 of them repeat donors, represent an alert for blood bank
246 safety in Amazonas state. Considering the complex TDR profiles
247 detected⁶ and the widespread early use of ART and pre/post
248 exposure ARV prophylaxis recommended by the Brazilian
249 Ministry of Health, new blood bank safety strategies may
250 be needed, as both viral load and antibody production can be
251 reduced and become negative upon early ART. This possibility

252 raises crucial public health blood transfusion concerns, espe-
253 cially in highly endemic areas as the Amazonas state, Brazil.
